EMERALDS FROM THE MANANJARY REGION, MADAGASCAR: INTERNAL FEATURES

By Dietmar Schwarz

Inclusions in emeralds from the Mananjary region in the eastern part of the island nation of Madagascar are reported and compared with inclusions in emeralds from other, especially African, localities. Although most of these internal features are similar to those found in emeralds from other schist-type deposits, Mananjary emeralds usually can be separated from emeralds from other localities by means of associations of certain mineral inclusions (especially talc, carbonates, amphiboles, and quartz) with specific types of fluid inclusions.

Emeralds from Madagascar

For many years, Africa has been one of the main producers of emeralds, with known schist-type deposits in Zambia, Zimbabwe, Mozambique, Tanzania, Egypt, and South Africa, as well as deposits formed in a special environment in central Nigeria. Significant quantities of fine emeralds (figure 1) have also been found in schists in the Mananjary region of Madagascar, a large island nation off the southeast coast of Africa (Schwarz and Henn, 1992). Until now, however, there has been little information in the gemological literature about the Mananjary emeralds and how their internal features compare with those of emeralds from schist-type deposits elsewhere.

According to knowledgeable sources (E. J. Pesch, Th. Eit, W. Spattenstein, and H. Hänni, pers. comms., 1993), the Mananjary region was the only emerald-producing area in Madagascar until about two years ago, when mining began at a small deposit discovered in the southern region of Madagascar near the town of Benenitra (about 150 km east of the city of Toliara; see figure 2). However, this new deposit produces only small, dark crystals (E. J. Pesch, H. Hänni, and G. Spagnoli, pers. comms., 1993) and is not discussed further in this article.

The Mananjary region represents a mining area of considerable potential and size. Important mines within this region include an unnamed alluvial emerald occurrence, about 50 km west-southwest of Mananjary, near the town of Ifanadiana (Sinhzanlar, 1981); the Ankadilalana mine, near the town of Kianjavato (Hanni and Klein, 1982); and the Morafeno mine, about 30 km south of Mananjary (Schwarz and Henn, 1992). There are actually numerous operations throughout the region. In the general area of the Morafeno mine, for example, Thomas (1993) reports visiting nine mines: Ambodirofia, Ambodibonary, Ambadamanino, Ambodibalzoly, Mororano, Ambodifandrilza, Mohotsana, Ambilanifitorana, and Ambodizainana.

The present article provides the first comprehensive description of the inclusion features of emeralds from the Mananjary region. It also compares these internal characteristics to those observed in emeralds from other localities. In many cases, these Madagascar emeralds can be distinguished from emeralds from other occurrences on the basis of their inclusions.

BACKGROUND
Emerald Occurrences in Madagascar. Beryl is one of the most important of the more than 50 gem minerals found on Madagascar (Chikayama, 1989). Aquamarine and other beryls from Madagascar have been known in Europe since French occupation of the island in 1883. Levat (1912) appears to have been the first to mention an occurrence of emerald in Madagascar. Lacroix (1932) provided the first detailed survey account of occurrences—both primary and secondary (i.e., alluvial)—of gem-quality beryl there. However, the primary emerald occurrences that are in the vicinity of the coastal town of Mananjary have been known for only about 20 years. Sinkankas (1981) mentioned an emerald occurrence about 50 km west-southwest of Mananjary and about 250 km southeast of Tananarive (now named Antananarivo), the capital of Madagascar, near the town of Ifanadiana (again, see figure 2). In this alluvial deposit, small rounded emerald fragments have been found together with kyanite.

Hanni and Klein (1982) described emeralds from the Anlazinilana mine, near the town of Xianjavato. They reported that these emeralds,
Emeralds from Madagascar, which originate from a mica schist, are similar to Zambian emeralds with respect to their blue-green color and optical properties. They described the emerald mining at that time as sporadic and carried out with primitive equipment.

Only during the last few years have the Morafeno occurrences, about 30 km southeast of the Ankadilalana deposit, been exploited commercially (figure 3). These deposits, which are also embedded in mica schists and subordinately in amphibole schists, are considered extensive and rich in emerald mineralization (Th. Eidt, pers. comm., 1993). At the beginning of the 1990s, the worked area around Mananjary comprised at least 50 km² (E. J. Petsch, pers. comm., 1993; Thomas, 1993). Mining is performed by independent miners and a number of small mechanized operations (figure 4). Precise figures for the quantity or value of emeralds produced to date are not available; most crystals range from one to three carats, but low-quality crystals up to 1,000 grams have been reported (E. J. Petsch, pers. comm., 1993).

Compared to emeralds from the African mainland, many of the stones from the Mananjary region are somewhat light in color; others are a bluer green, similar to Zambian emeralds. See figure 4.
Figure 3. As this overview of one mining operation shows, some deposits in the Morafeno region have been worked extensively in recent years. Photo by E. Julius Petsch, of Julius Petsch Jr., Idar-Oberstein.

Figure 4. At Morafeno, this mining company uses a backhoe to reach the emerald-bearing schists. Photo by E. Julius Petsch, of Julius Petsch Jr., Idar-Oberstein.

Figure 1. The crystals range from opaque to transparent, and nice cabochons can be cut from translucent rough (figure 5). Generally, the emerald crystals are found embedded in the host mica or amphibole schist or in quartz (figure 6). Additional information on this locality, the material produced, and the gemological properties of these emeralds (which overlap those of Fe- and Cr-rich emeralds from other schist-type deposits) can be found in Schwarz and Henn (1992).

Previous Inclusion Studies. To date, the following mineral inclusions [see table 1] and other internal features have been reported for emeralds from Madagascar. In the stones from Ankadifanana, Henn and Klein (1982) identified brown biotite, muscovite, apatite, hematite, goethite, quartz, ilmenite, tourmaline, liquid/gas two-phase inclusions, and color zoning. Campbell (1991) observed goethite and hematite, as well as limonite and phlogopite, in a cabochon-cut emerald from Madagascar that also showed color zoning and negative crystals. M. L. Delo-Lasir and J. P. Poirot (pers. comm., 1991) identified the following mineral inclusions in emeralds from Madagascar by means of Raman spectroscopy: carbonates [ankerite], quartz, phlogopite, apatite, illu-
orite, pyrite, and pyrrhotite. Kleyenstüber (1991) also reported the internal features of Madagascar emerald from the same rough that yielded the sample described by Campbell: elongated hollow growth channels with a rectangular outline; a large hexagonal crystal with a distinct yellow-to-green pleochroism (possibly tourmaline or apatite); booklets of mica platelets (phlogopite and, possibly, muscovite); negative crystals, usually filled with a liquid and gas; and minute to submicroscopic inclusions of a potassium feldspar (probably microcline) and quartz.

Thomas (1993) did not note any mineral inclusions in stones from An ladenana specifically, but only spiral stress fractures and numerous liquid-filled vei- and feather-like inclusions. He did list some mineral inclusions for emeralds from the Mananjary region (but did not indicate the methods by which he identified them). These include biotite platelets; euhedral transparent crystals of a colorless cubic mineral, possibly rhodizite; and small, well-formed black spinel crystals. Another group of Mananjary emeralds showed oriented ‘blocky’ negative crystals and dense parallel groups of slender acicular negative crystals. In stones from Morafeno, Thomas described ‘Saturn-like’ inclusions comprising a rather large, tabular negative crystal cavity surrounded by a partially healed liquid-and-gas stressed halo. ‘Fingerprints’, a few oriented, slender, rod-like inclusions; and small, transparent, cubic crystals (rhodizite!).

MATERIALS AND METHODS

More than 100 emerald crystals and crystal fragments (see, e.g., figure 7) were examined for this study. They were purchased in the Mananjary mining region by Idar-Oberstein gem dealers (some of whom are involved in the actual mining) and Dr. Thomas Eidt. They reportedly came from an area of at least 25 km² near the town of Morafeno and are representative of the emeralds recovered from the Mananjary deposits. Most of these samples ranged from 0.5 to 3 ct.

For this research project, the inclusions were first described and classified using a binocular Schneider immersion microscope with Zeiss optics. Then all of the different types of inclusions were photographed with the samples immersed in benzoic acid. Next, samples with mineral inclusions that appeared to be typical were polished down until the mineral inclusions to be analyzed were exposed at the surface. A Philips XL 30 scanning electron microscope fitted with an EDAX energy-dispersive X-ray spectrometer (SEM-EDS) was then used for chemical analysis of these inclusions.

**OBSERVATIONS AND RESULTS**

Many different mineral inclusions were identified. Most, but not all, have also been seen in emeralds from other locations in Africa and elsewhere. Table 1 lists the mineral inclusions seen in Mananjary emeralds and the reports on which the Madagascar identifications were based, as well as some other countries that have produced emeralds with similar features (and the corresponding references). Some unusual fluid inclusions have also been seen in the Mananjary stones.

**Quartz**. About 35% of the samples contained one or more of the following four types of quartz inclu-
ions, which were categorized on the basis of their morphology and manner of occurrence:

1. Transparent, colorless, elongated, prismatic crystals oriented with their c-axis parallel to the c-axis of the host emerald, often associated with primary fluid inclusions. These occurred as isolated crystals, irregularly distributed throughout the host crystal, or dispersed over the planes of healing fissures. Some samples contained large numbers of these quartz inclusions in their central regions (figure 8).

2. Angular or somewhat rounded grains, some almost spherical (figure 9). These were less commonly associated with fluid inclusions than was the first type of quartz inclusion. Groups of such grains were concentrated in certain areas.

3. Irregularly rounded crystals, some of which had a badly corroded rough surface.

4. Isolated crystals that were probably daughter crystals of former fluid-filled cavities that were opened during sample preparation (figure 10). These quartz crystals were often intergrown with other mineral inclusions, including talc, mica, amphibole, chlorite, carbonates (figure 11), and beryl. Such aggregates were often accompanied by unhealed tension fissures. In some cases, the quartz inclusions were covered by a substance that appeared black or opaque in transmitted light (again, see figure 9).

Quartz inclusions are mentioned in almost all

Figure 8. About a third of the Mananjary emerald crystals examined contained inclusions of quartz. Often, they occur as numerous colorless, transparent, elongated, prismatic crystals oriented in the direction of the c-axis of the host emerald. Many quartz crystals are associated—or intergrown—with growth tubes containing primary fluid inclusions. Immersion, magnified 20x.

Figure 9. Other quartz inclusions in the Mananjary emeralds were angular or somewhat rounded. One of the large crystals shown here in a slice cut from one of the samples (the yellow color is from the immersion liquid) is partly covered by a substance that appears black in transmitted light; the other contains what appears to be a small secondary beryl crystal. Note the small, almost spherical quartz crystal toward the bottom of the photomicrograph. Magnified 70x.

Figure 10. This scanning electron micrograph shows a quartz crystal as part of a fluid inclusion in a Mananjary emerald. When the host crystal was polished down and the cavity exposed at the surface, the other—gaseous and liquid—phases of the inclusion were lost. Magnified 500x.
Quartz-inclusion types 1 and 2 resemble features observed in many Brazilian emeralds from the Itabira/Nova Era mining region (compare Hanni et al., 1987; Schwarz et al., 1988a). Consequently, quartz inclusions are of little value in determining the locality of the host emerald.

Mica. The most common mineral group observed in the Mananjary emeralds, mica was seen in about half of the samples. In these emeralds, mica occurs mostly as randomly distributed transparent crystals that may appear dark brown in transmitted light. Usually somewhat rounded, they also may have an almost perfect (pseudo-) hexagonal outline (figure 12); they often appear as booklets of thin platelets (figure 13). Chemical analyses showed that most of the micas in the Mananjary emeralds belong to the biotite/phlogopite series (with about 15–20 wt.% MgO, 5–15 wt.% FeO, and 10–12 wt.% K2O), although the Mg- and Fe-poor species muscovite was also identified.

Mica inclusions have been identified in all reports published to date on Madagascar emeralds, and by the author in emeralds from almost all African occurrences (Zambia, Zimbabwe, Tanzania, Mozambique, South Africa, and Egypt). Worldwide, most emerald deposits are related to mica schists. Consequently, biotite/phlogopite micas are the most common mineral inclusions in emeralds. They have been identified, for example, in emeralds from several localities in Brazil: the Belmont mine (see Hanni et al., 1987) and Capocizzana deposit (Schwarz et al., 1988a), in the state of Minas Gerais; the Fazenda Boa Esperança, Taúá, in Ceará (Schwarz et al., 1988b); the Carnaiba (Schwarz and Eidt, 1989) and Socoto mining areas (Schwarz et al., 1988b) in Brazil; and the Masahatta mining area in Egypt (Schwarz and Eidt, 1989) and Socoto mining areas (Schwarz et al., 1988b).
Many of the Mananjary emeralds examined contained long, prismatic, stalk-like, green amphibole (actinolite/tremolite) crystals with a system of fissures that ran nearly parallel to the basal face. Note also in this inclusion scene the transparent, colorless, rounded quartz crystal on the far right. Immersion, magnified 50x.

Mica inclusions have also been described in emeralds from the Poona region and from Muzo in Western Australia (Schwarz, 1991a), from the Ural Mountains in the Russian Federation (Schwarz, 1991b), and from the Habach Valley (Habachtal) in Austria (Grundmann, 1991; Schwarz, 1991b). Amphiboles. Until this study, minerals of the amphibole group had not been described as inclusions in Madagascar emeralds (see, e.g., Thomas, 1993). The author has seen them in emeralds from other African localities (the Sandawana/Machingwe mining area in Zimbabwe, the Ndola Rural district in Zambia, and the Leydsdorp district in South Africa), as well as the Carnaiba, Socoto, and Fazenda Boa Esperança mining areas in Brazil, among others. Although mica schists are the most common host rocks for emeralds, often these schists grade into amphibole-bearing or amphibole schists. This explains why amphiboles (mostly of the actinolite/tremolite series) are frequent inclusions in many emeralds and are sometimes the dominant inclusion mineral (as, for example, in emeralds from the Zeus claims in the Sandawana region of Zimbabwe).

Amphibole crystals were seen in about 20% of the emeralds in this study. The amphibole crystals observed belong to the actinolite/tremolite series, with FeO and MgO each about 10-15 wt.%. The sum (FeO + MgO) in different crystals was found to be constant at about 26 wt.%. The actinolite/tremolite crystals are green, with a long, prismatic, stalky habit. Often they show systems of nearly parallel planes that are slightly inclined with respect to the main axis of the crystals [figure 14]. This results in the bamboo-like appearance typical of actinolite/tremolite inclusions in emeralds from other occurrences. The random distribution of these crystals and the fact that they are often broken at their extremities suggests that they are protogenic, that is, that they formed before the host emerald.

The relative distribution of mica and amphibole crystals in the Mananjary emeralds is very irregular. Some emeralds contain many mica crystals and are practically free of amphiboles, others contain numerous amphibole crystals but practically no mica, and many contain amphibole and mica in almost equal quantities. This reflects the varying composition of the host rock in which the emeralds formed: a mica schist, an actinolite/tremolite schist, or a combination of both. It is likely that amphiboles were not reported in prior articles on inclusions in Mananjary emeralds because the samples studied were taken only from mica schists and not from amphibole schists.

Carbonates. About 15% of the samples contained carbonate inclusions, which are also relatively rare.
in emeralds from other African localities. M. L. Delé-Lasir and J. P. Poirot (pers. comm., 1991) have identified carbonates in emeralds from the Transvaal in South Africa (as did Roulet, 1956), as well as from Zambia (dolomite, calcite) and Sandawana (dolomite). Although some of the Mananjary-emerald carbonate inclusions were relatively well-developed rhombohedral crystals (figure 15), most were irregular or rounded grains; in general, they appeared transparent and colorless. The rare prismatic carbonate crystals observed usually appeared black or opaque in transmitted light because they contained numerous minute inclusions. Surface corrosion made some carbonate crystals appear slightly brown in transmitted light.

The carbonate inclusions are usually calcite crystals with small amounts (<1-2 wt.%) of manganese and/or iron. However, chemical analyses also identified Fe-dolomite and a calcite containing relatively high FeO and small amounts (~1%) of magnesium and manganese. Frequently, the carbonate crystals were intergrown with other mineral species (most commonly quartz and talc; again, see figure 11).

Feldspar. Feldspar crystals were identified in about 5% of the Mananjary emerald crystals. Surface corrosion and the presence of minute inclusions (of quartz, among other minerals) gave some of these typically transparent and colorless crystals a somewhat darker (sometimes brown) appearance in transmitted light. They were usually irregular in shape and often very rounded. The feldspars analyzed varied from almost pure albite (Na-feldspar) to a plagioclase containing about 5 wt.% Na₂O and 6-7 wt.% CaO. Sometimes, the feldspars were intergrown with quartz or mica. Kleyenstuber (1991) described a K-feldspar inclusion in a Madagascar emerald.

As table 1 indicates, feldspar inclusions also have been observed (by the author and others) in emeralds from Zimbabwe and Nigeria, as well as from Tanzania. Representatives of this mineral group are also known in emeralds from other occurrences, such as Colombia and the Swat region of Pakistan; the Belmont mine, Carnaiba, and Socotó, in Brazil; the Ural Mountains of the Russian Federation; and the Habach Valley of Austria.

Talc. Before this study, talc had not been reported as an inclusion in Madagascar emeralds. Talc inclusions were identified in about 20% of the samples. Talc was observed in four different forms: (1) uncommonly, as fibrous aggregates, sometimes with a sheaf-like aspect (figure 16); (2) as irregular-shaped scales dispersed over fracture planes (possibly introduced in conjunction with an epigenetic filling process); (3) as pseudohexagonal transparent green platelets; and (4) intergrown with other inclusion minerals (e.g., quartz, pyrite). The Sandawana/Machingwe (Zimbabwe) region is the only other place in Africa where talc crystals have been found in emeralds—and then only rarely. Therefore, the presence of talc (especially in its fibrous or sheaf-like form) may be useful in separating Mananjary emeralds from those from other African localities. However, the author has found that talc is one of the most common mineral inclusions in emeralds from the talc-carbonate schists of Santa Terezinha de Goias, Brazil, and from the Swat region, Pakistan (see table 1).

Beryl. Inclusions of beryl typically occur either as colorless, irregular, strongly corroded crystals or as well-developed, heavily included prisms that appear white in darkfield illumination. In addition, some

![Figure 16. These fibrous aggregates are representative of the talc inclusions seen in Mananjary emeralds. Magnified 50x.](image-url)
Figure 17. In reflected light, this pyrite grain in a Mananjary emerald shows the yellow color and metallic luster typical of this mineral. Immersion, magnified 50x.

Beryl was observed as rounded grains in quartz inclusions (again, see figure 9), which indicates that at least two beryl "generations" (with different features) occurred in the area of the emerald mineralizations. Beryl and/or emerald crystals have been identified by the author and others as inclusions in emeralds from several occurrences (e.g., Colombia, Nigeria, Pakistan, and various localities in Brazil), so their presence is of little diagnostic value when determining the origin of an emerald.

Chlorite. Chlorite was observed in only a few samples, as small grains or platelets intergrown with quartz and/or mica. Although not previously reported in Madagascar emeralds, chlorite has been seen by the author in emeralds from Zambia, Zimbabwe, and the Itabira/Nova Era region in Minas Gerais, Brazil. Chlorite has also been seen in material from Pakistan and elsewhere in Brazil (Carnaiba and Socotó), so their presence is of little diagnostic value when determining the origin of an emerald.

Molybdenite. Identified in less than 5% of the Mananjary emeralds, molybdenite crystals occur as gray to silver platelets with a typical metallic luster. They may be slightly rounded or show a well-developed hexagonal outline (again, see figure 13). Molybdenite is known as an inclusion in emeralds from many areas, such as the Transvaal in South Africa, various Brazilian deposits, the Habach Valley of Austria, and the Swat Valley of Pakistan (again, see table 1). Molybdenite has not been described before in emeralds from Madagascar.

Pyrite. Observed in less than 5% of the Mananjary samples, pyrite— as determined by X-ray diffraction analysis of a representative iron sulfide inclusion— appeared a typical metallic yellow under reflected light (figure 17). Most of the pyrite crystals were well developed. Chemical analyses revealed about 2 wt.% NiO and small amounts (<0.5 wt.% ZnO). M. L. Dele-Last and J. P. Poitot (pers. comm., 1991) have identified pyrite in emeralds from Mozambique as well as from Madagascar. Pyrite has been seen frequently by the author in emeralds from different types of occurrences, including Colombia, as well as the Santa Terezinha, Carnaiba, and Socotó deposits in Brazil. Pyrite has also been reported in emeralds from the Transvaal in South Africa, the Habach Valley in Austria, and the Swat Valley of Pakistan (see table 1).

Barite. Barite was observed in only two samples, as very small, colorless, transparent grains of irregular shape. Apparently a very rare inclusion in emerald, it has been reported in emeralds from only two other localities—Colombia and Santa Terezinha de Goiás, Brazil (Mendes and Swirner, 1988). It has not been reported for Madagascar emeralds before.

Tourmaline. Tourmaline was observed in less than 5% of the Mananjary emeralds. Those crystals seen were typical trigonal prisms, which chemical analysis showed to be members of the dravite-schorl series. Tourmaline inclusions, although by no means common in emerald, have been identified previously in Madagascar emeralds (Hanni and Klein, 1982) and by the author and others in emeralds from widely different occurrences elsewhere: Zambia and Zimbabwe in Africa, the Ural Mountains of the Russian Federation, Carnaiba and Socotó in Brazil, and the Habach Valley in Austria (see table 1).

Fluid Inclusions. One or more of the following types of fluid inclusions were observed in most of the Mananjary samples:

Emeralds from Madagascar
Numerous minute fluid inclusions (some associated with quartz—again, see figure 8—and others with an unidentified material) contained in healed to partly healed fissures.

Larger fluid or mineral inclusions accompanied by black-appearing spheres—actually clusters of numerous minute fluid inclusions (figure 18).

Primary fluid inclusions, often associated with quartz crystals. These inclusions were typically elongated—that is, within growth tubes—in a direction parallel to the c-axis of the host emerald (again, see figure 8). Most had well-developed rectangular or square outlines (negative crystals; figure 19); others were rounded and strongly resembled gas bubbles. Most of the fillings were two-phase (liquid and gas), but three-phase inclusions were also observed. These fluid inclusions may show unusually strong relief and, in transmitted light, often are so dark as to appear opaque.

When large numbers of primary fluid inclusions occur in fine, elongated cavities (figure 8), they are responsible for the so-called rain effect that gives a silk-like sheen to cabochon-cut emeralds. In some cases, they can even generate chatoyancy.

Other Microscopic Features. Other internal features observed in the Mananjary emeralds include:

- Color zoning: normally a light core and a dark outer zone
- Growth strie parallel to the prism faces
- Concentrations of inclusions in certain areas of the host crystal (e.g., a central zone with numerous minute quartz crystals)
- Systems of essentially parallel fractures that are only partly healed
- Various types of fissures: delicate healed fissures with small fluid inclusions (often almost flat or slightly wavy, almost parallel to one another, and sometimes oriented parallel to the basal pinacoid of the host emerald); unoriented, unhealed fissures (partly filled with an unidentified material), and unoriented, healed fissures with numerous minute "particles" (probably minute fluid inclusions).

DISCUSSION AND CONCLUSIONS

Although precise production figures for the emerald occurrences in the Mananjary region are not available, from the size of some of the mechanized operations it can be concluded that many thousands of carats have been mined. In addition, geologic conditions appear to favor the discovery of larger mineralization sites (Th. Eidt, pers. comm., 1993). Because the physical and chemical properties of Mananjary emeralds fall within the ranges for emeralds from most other localities, the emeralds of this region are best identified by their internal features.

Mananjary emeralds come from a geologic environment that is characterized by the association of different metamorphic schists (principally biotite/phlogopite schists and subordinately amphibole-bearing or amphibole schists) and pegmatitic veins (that is, a "schist-type deposit," where pegmatites or pegmatoid veins are the primary source of the element beryllium). Thus, their inclusion features are very similar to those in most emeralds from other schist-type deposits (e.g., quartz, platelets of biotite/phlogopite mica, rods or needles of actinolite/tremolite, platelets or grains of chlorite, and feldspar crystals). These types of inclusions may occur, for example, in emeralds from Zambia.

Emeralds from Madagascar

Figure 18. Spherical clusters of numerous fluid inclusions that appeared black in transmitted light were relatively common in the Mananjary emeralds but have not been reported in emeralds from many other localities. Immersion, magnified 50x.
(Ndola Rural district), Zimbabwe (Sandawan/Machingwe mining region), South Africa (Lyd astrology/Transvaal), and Brazil (e.g., Bahia and Minas Gerais). Other mineral inclusions—such as apatite, biotite, ilmenite, tourmaline, pyrite, or molybdenite—also can be seen in emeralds from other localities and different formation environments. However, they are so rare that they are of little diagnostic value.

Even with all of these restrictions, most Madagascar emeralds can be separated from those from other African localities. What is most characteristic is the association of certain mineral inclusions (especially talc, carbonates, amphiboles, and quart z) with specific types of fluid inclusions, such as fluid inclusions with quartz crystals, in healing fissures; fluid inclusions in large numbers, forming spherical black clusters, and primary fluid inclusions that show very strong relief and appear almost opaque, or are rounded and resemble gas bubbles. Of the other African localities, only Zambian emeralds have fluid inclusions that are similar to the primary fluid inclusions, with well-developed rectangular or square outlines (negative crystals), seen in the Madagascar stones.

As previously mentioned, the fluid inclusions in emeralds from the Itabira/Nova Era region in Minas Gerais, Brazil (Belmont and Capoeirana mining fields), are similar to those observed in the Madagascar samples. Separating emeralds from these two sites could be very difficult. The presence of talc—especially when it appears in a fibrous or sheet-like form—is a good diagnostic feature for Mananjary emeralds. So far it has been observed only very rarely in emeralds from one other African locality [the Sandawan/Machingwe mining area of Zimbabwe]. Although talc is seen in Madagascar emeralds from other localities (e.g., Santa Terezinha de Goiás, Brazil, and the Swat region of Pakistan) the other internal features of these emeralds are so different that they are easily separated from Mananjary stones.

The ultimate authority on diamonds and the diamond industry is now available for consultation.

Presenting

The GIA Diamond Dictionary, 3rd Edition

Completely revised and updated + More full color photos, drawings and charts + 100+ newly commissioned maps + More facet diagrams + More international in scope

The GIA Diamond Dictionary, 3rd Edition, contains the knowledge and expertise of an unprecedented team of industry leaders — gemologists, cutters, designers, bench jewelers, historians, geologists, physicists, and chemists from the South African grasslands to the Australian outback. It’s the most detailed examination of the vast, complex and diverse world of diamonds ever published. No jewelry professional and/or student of gemology can afford to be without it.

To obtain your copy of The GIA Diamond Dictionary, 3rd Edition, for only $99.50 (plus tax and shipping), call today toll-free:
